Outline

- Background
- Methods
- Discussion
- Conclusion

- ▶ This dataset concerns a localised outbreak of *Neisseria* gonorrehoeae in an indigenous community located in Alberta, Canada. it was originally analyzed in a paper by P De, et al. (2004), in which they used measures of network centrality (e.g. information centrality) to determine the association between the risk of infection between members of the network and their position within the network itself.
- ▶ The network consists of 89 individuals, both male and female, 17 of whom were found to be patrons of a local bar in the area.
- ▶ This work expands upon the original analysis by looking at other types of network centrality such as eigenvector centrality, as well as applying exponential random graph modeling (ERGM) to the network in order to quantify the effect of various attributes of the network (e.g. gender, bar attendance).

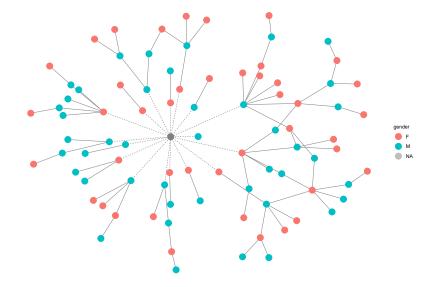

- Gonorrhea is a sexually transmitted disease/infection (STD/STI) which can be transmitted orally, vaginally or anally.
- According to the Centers for Disease Control and Prevention, about 1 in 5 people in the United States have a STI, totalling nearly 68 million infections in 2018.
- ▶ Of the 26 million new infections in 2018, it is estimated about 1.6 million of them were gonorrhea.
- Although it can have many serious side effects, it can also be symptomless, leading to individuals unknowingly infecting their partners.

- Although the adjacency matrix for the data allowed us to analyze the network as a directed network, we thought it prudent to symmetrize the matrix (as was done in P De et al.)
- ▶ 2 of the datapoints were missing information regarding their gender so we dropped them from the dataset. They both had a degree of 1 so it wasn't thought that their exclusion would be impactful. This left 46 males and 46 females in the network.

- Data on sexual networks can be collected either egocentrically or sociometrically.
- ▶ In the former case, the method involves interviewing the ego, and getting information regarding their alters (sexual partners) without in turn contacting their alters.

The connected network with the bar as a node

The connected network with the bar as a node

- ► There are 91 total edges in this network, with 17 of them being between the bar and individuals, leaving 74 of them to be between individuals.
- ▶ Of these 74, 67 (approx. 90.5%) of them are M-F edges, 6 of them are M-M, and 1 of them is F-F.
- ▶ Of these 74, 36 (approx. 48.6%) of them are between bar-attendees and non-attendees, and 38 (51.3%) are between non-attendees and other non-attendees only.
- Note that none of the bar attendees have ties to other bar attendees at all.

Distribution of ties

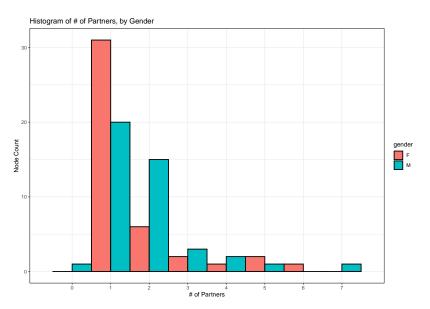

Figure 1: Histogram of partners, by gender.

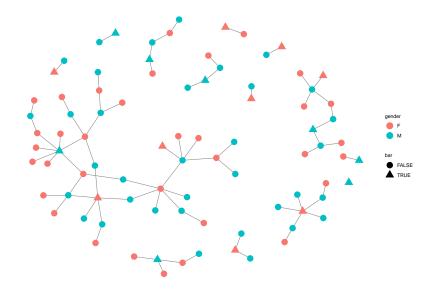

Methods

- Degree Centrality
- ► Eigenvector Centrality
- ► Katz Centrality
- Average Distance
- Exponential Random Graph Model (ERGM)

Exponential Random Graph Model (ERGM)

- While measures such as network centrality and network density can provide us some information about the characteristics of a network, in the case of a sexual network in which ties have an explicitly social component to them, an ERGM which incorporates the attributes of actors within the network can be more informative.
- When modeling the ERGM for this network, the bar node was redacted so that the network could be a one-mode network, and instead attendance of the bar was assigned to the vertices as an attribute, as was gender. This model was saved as gonnet_net_nobar in R.

The disconnected network

The disconnected network

- ▶ There are about 9 or so subcomponents of this graph; notice that the largest among them has 3 bar attendees within it, 2 of whom have at least 5 ties to other individuals.
- Notice there is one isolate where a male node attended the bar but otherwise has no ties to any other node.
- There also a a series of smaller sub-components where there is only one edge between two nodes, one of whom is a bar attendee.
- ▶ Note the presence of a "6-cycle" in the largest subcomponent, in which 6 separate nodes are jointly connected through one another. This is the only such appearance of a k-cycle in the entire network.
- ► The largest subcomponent of the graph includes 38 of the 86 nodes in the network, or approximately 44% of all egos.

Fitting the ERGM model

- ▶ When fitting the ERGM model, first we started with the simplest model that only modeled the number of edges (this would be akin to an intercept-only model in logistic regression). We then built several more models which only had one parameter, and then compared the Akaike Information Criteria (AIC) of the models to determine which among these model parameters were worth including.
- Among the model parameters fit were homophily (nodematch), heterophily (nodemix) and degree (degree).

Fitting the ERGM model

Akaike Information Criterion (AIC)

- The Akaike Information Criterion (AIC) is an estimator of out-of-sample prediction error.
- ▶ We use it as a means of model selection, where we generally opt to select the model with the lowest AIC.

$$AIC = -2\ln(L) + 2k$$

▶ Where *L* is the likelihood of the model, and *k* is the number of parameters.

Fitting the ERGM model

```
## Starting maximum pseudolikelihood estimation (MPLE):
## Evaluating the predictor and response matrix.
## Maximizing the pseudolikelihood.
## Finished MPLE.
## Starting Monte Carlo maximum likelihood estimation (MCMLE):
## Iteration 1 of at most 60:
## Optimizing with step length 1.0000.
## The log-likelihood improved by 3.0664.
## Estimating equations are not within tolerance region.
## Iteration 2 of at most 60:
## Optimizing with step length 0.7979.
## The log-likelihood improved by 1.2443.
## Estimating equations are not within tolerance region.
## Iteration 3 of at most 60:
## Optimizing with step length 1.0000.
```

The log-likelihood improved by 0 9990

- ➤ A likelihood ratio test is a method to compare a full model to a nested model, where the nested model has some subset of the same parameters as the full model.
- When comparing a full model to a nested model, we can conduct a Likelihood Ratio Test, in which we take the ratio of the maximum likelihoods of both the full model and the nested model, in order to determine whether the nested model explains the data as well as the full model.

- $\lambda = \frac{\mathcal{L}_s(\hat{\theta})}{\mathcal{L}_g(\hat{\theta})}$ $LRT = -2 \ln \lambda$
- where $\mathcal{L}_s(\hat{\theta})$ is the maximized log-likelihood for the nested model, and \mathcal{L}_g is the maximized log-likelihood for the full model.

- ► H₀: The nested model fits the data as well as the full model. i.e. The nested model is preferred.
- \blacktriangleright H_A : The nested model does not fit the data as well as the full model. i.e. The full model is preferred.
- We reject the null hypothesis H_0 when the test statistic falls within the rejection region of a chi-squared distribution with degrees of freedom k where k is the difference in the number of parameters between the two models. Otherwise, we fail to reject H_0 .

```
## Likelihood ratio test
##
Model 1: gonnet_net_nobar ~ edges + degree(d = c(1:3)) + nodemix("gender") +
## nodematch("bar")
## Model 2: gonnet_net_nobar ~ edges + degree(d = c(1:3)) + nodemix("gender")
## #Df LogLik Df Chiaq Pr(>Chiaq)
## 1 7 -302.21
## 2 6 -306.06 -1 7.7033  0.005512 **
## ---
## "---
## Signif. codes: 0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
```

Model Selection

- The chi-squared test statistic for the likelihood ratio test had a p-value of \approx 0.003, which is less than our significance level $\alpha=0.05$.
- Hence we have enough evidence to reject the null hypothesis and conclude that full model, which has the homophily attribute for bar attendance in addition to the heterophily attribute for gender and the degree attribute, is the preferred model.

Model diagnostics

```
## Call:
## ergm(formula = gonnet_net_nobar ~ edges + degree(d = c(1:3)) +
      nodemix("gender") + nodematch("bar"))
##
